ABSTRACT

We report the discovery by M. Linnolt on JD 2455665.7931 (UT 2011 April 14.29) of the sixth eruption of the recurrent nova T Pyxidis. This discovery was made just as the initial fast rise was starting, so with fast notification and response by observers worldwide, the entire initial rise was covered (the first for any nova) with fine time resolution and in three filters. The speed of the rise peaked at 9 mag/day, while the light curve is well fit over only the first two days by a model with a uniformly expanding sphere. We also report the discovery by R. Stubbings of a pre-eruption rise starting 11 days before the eruption, peaking 1.1 mag brighter than its long-time average, and then fading back towards quiescence five days before the eruption. This unique and mysterious behavior is only the fourth known (with V1500 Cyg, V533 Her, and T CrB) anticipatory rise/dip closely spaced before a nova eruption. We present 19 timings of photometric minima from 1986 to February 2011, where the orbital period is fast increasing with $P/\dot{P} = +313,000$ years. From 2008-2011, T Pyx had a small change in this rate of increase, so that the orbital period at the time of eruption was 0.07622916±0.00000008 days. This strong and steady increase of the orbital period can only come from mass transfer, for which we calculate a rate of $10^{-6.0\pm0.5}$ $M_{\odot}$ yr^{-1} for mass leaving the companion star. We report 6114 magnitudes between 1890 and 2011, for an average $B = 15.59 \pm 0.01$ from 1967-2011, which allows for an eruption in 2011 if the blue flux is nearly proportional to the accretion rate. We present a model for the infrared-to-X-ray emission during quiescence as being from a 34,000 K blackbody nearly filling the Roche lobe (caused by the very high accretion rate creating an extended envelope around the accretion column) plus a $\nu^{0.9}$ non-thermal component (from the optically-thin outer and circumbinary regions).

Subject headings: novae, cataclysmic variables - stars: individual (T Pyx)

1. Introduction

T Pyxidis (T Pyx) was the first discovered recurrent nova (RN) with three known eruptions, and this over a dozen years before any other RN had even their second discovered eruption (Schaefer 2010). T Pyx is one of the quintessential RN, with six eruptions in 1890, 1902, 1920, 1944, 1967, and now 2011. Over the past few decades, the quiescent magnitude of T Pyx has been near V=15.5, while peaking at V=6.4 (Schaefer 2010). T Pyx is slow among RNe, with its overall rise taking 40 days and the decline by three magnitudes from the peak (t_3) taking 62 days (Schaefer 2010). T Pyx is one of two RNe with an orbital period (P=0.076 days; Schaefer et al. 1992; Patterson et al. 1998; Uthas et al. 2011) that is inside or below the period gap. T Pyx is the only RN that has a nova shell, and this shell has a surprisingly slow expansion velocity plus a structure of thousands of discrete knots (Duerbeck & Seitter 1979; Williams 1982; Shara et al. 1989; 1997). The homologous expansion of the individual shell fragments proves that they suffer no significant deceleration, and the expansion velocities, viewed over 13 years by *Hubble Space Telescope*, prove that the nova shell was ejected in the year 1866±5 at a velocity of 500-715 km s^{-1} (Schaefer et al. 2010a). This velocity is greatly too low to be from a RN event, and with the measured mass in the shell ($\sim 10^{-4.5}$ $M_\odot$) being much greater than is possible for a RN event, we know that the 1866 event must have been a normal classical nova eruption with a very long time of prior quiescence (Schaefer et al. 2010a).

A key and unique fact about T Pyx is that its quiescent brightness has been secularly fading from 1890 to 2011 (Schaefer 2005). Before the 1890 eruption, archival plates show T Pyx to be constant at B=13.8, the next four inter-eruption intervals have B-band magnitudes of 14.38, 14.74, 14.88, and 14.72, while after the 1967 eruption the quiescent B magnitude fades from 15.3 (around 1968) to 15.5 and fainter (from the 1980's until 2011). This secular decline is fundamental for understanding the evolution and fate of T Pyx, as well as the timing of the eruptions.

T Pyx has long been a perplexing system, because there was no known way to combine a short orbital period and a high accretion rate into one system. (The accretion rate must be high, $\sim 10^{-7}$ $M_\odot$ yr^{-1}, so as to provide enough mass to trigger eruptions with a typical recurrence time interval of two decades.) That is, a binary with a period below the gap should have angular momentum loss only from gravitational radiation, and this will lead to an accretion rate many orders of magnitude smaller than required (Patterson 1984). This dilemma was solved by Knigge et al. (2000) who realized that the high accretion rate could be powered by a hot source on the white dwarf that is irradiating the companion star. For T Pyx, this idea was extended by Schaefer et al. (2010a), where the classic nova eruption of 1866 started a high accretion rate which drives a largely self-sustained supersoft source (with nuclear burning on the surface of the white dwarf). This mechanism can only work for binaries with short orbital periods and where a substantial magnetic field channels the material into a small area. The secular fading demonstrates that the supersoft source is not fully self-sustaining. Schaefer & Collazzi (2010) generalizes this situation to a whole class of stars, called V1500 Cyg stars, which suffer this same secular fading after their eruptions, and which also have short orbital periods and highly magnetized white dwarf stars. So the picture we have for T Pyx is that it started out as an ordinary cataclysmic variable with a long period of quiescence, then an ordinary nova eruption in 1866, which ignited a supersoft X-ray source whose irradiation drives a high accretion rate and hence recurrent nova eruptions. Over time, the accretion rate declines and the quiescent brightness fades.

By far the most important question relating to RNe is whether they are the progenitors of Type Ia supernovae. RNe are one of the best progenitor candidate classes, because they certainly have white dwarfs near the Chandrasekhar mass being fed with a very high accretion rate. Nevertheless, T Pyx (and any short-period RNe) cannot be a Type Ia progenitor (Schaefer et al. 2010a; Schaefer 2010). The reason is that the ordinary nova eruption in 1866 easily dominates the dynamics of the system, and ordinary nova eruptions eject much more mass than has been accreted by the white dwarf, so the white dwarf is actually loosing mass and will not become a supernova. Another way of saying this is that the secular fading shows that the interval during which T Pyx is a RN is short, perhaps under two centuries, and thus will have little effect even if the RN event causes a net gain of mass on the white dwarf. The long-period RNe remain as strong progenitor candidates (due to their high accretion rate being driven by the evolution of the donor star so as to be sustained and long in duration), but the short-period RNe cannot sustain the high accretion and so are not supernova progenitors.

The secular fading is also critical for understanding the timing and triggering of the RN events. Schaefer (2005) demonstrated that the inter-eruption intervals during which the quiescent magnitude was faint on average lead to a long time between eruptions, while a bright interval lead to a short time between eruptions. The physics is simple, with the amount of accreted mass required to trigger an eruption being constant for any one RN, with the accretion rate being given by the blue flux dominated by the accretion disk, so that a high quiescent brightness implies a high accretion rate and a short interval needed to accrete the trigger mass. With calibration from prior inter-eruption intervals, it becomes possible to predict the approximate date of upcoming eruptions. As such, Schaefer (2005) predicted that U Sco would erupt in 2009.3±1.0, and this advance notice allowed for an incredible coverage of the eruption in 2010.1, so that this now is the all-time best observed nova event (Schaefer et al. 2010b). Schaefer (2005) also predicted that the next eruption of T Pyx would be in 2052±3, while Schaefer et al. (2010a) extended this to predict that the next eruption will be after the year 2225. This prediction was shown to be horribly wrong by the T Pyx eruption in 2011, so the issue now is to understand where the prediction went wrong.

2. Discovery of the 2011 Eruption

Starting with the 1890 eruption, the inter-eruption intervals were 11.9, 17.9, 24.6, and 22.1 years (Schaefer 2010). In the middle 1980's many people around the world (including many of the authors of this paper) realized that T Pyx 'should' go off any year now. The simple logic was that the prior inter-eruption interval was 22 years, and 22 years after the 1967 eruption placed the expected eruption around 1989. Due to this, many of the world's best observers kept T Pyx under nightly watch.

As the 1990's stretched on, the expected eruption did not occur. Vigilance was maintained and occasional public exhortations were published in many journals. Any eruption after 1967 would certainly have been discovered because the T Pyx eruption duration is two-thirds of a year and so no eruption would have been missed due to observational gaps. By the year 2005, the interval since the prior eruption extended to 38 years, with no explanation for this long delay.

Schaefer (2005) provided the explanation. The key point was that T Pyx has been declining overall in brightness ever since before the 1890 eruption, and this means that the accretion rate in the system was declining, so that it would take longer to accumulate the trigger mass on the surface of the white dwarf. In particular, from the 1944 to the 1967 eruption the average B-band magnitude was 14.72 ± 0.03, while from 1967 to 2005 the average B-band magnitude was 15.49 ± 0.01 mag. The blue flux from T Pyx is entirely dominated by the accretion disk, so the B-band flux is determined by the accretion rate. The dimming by 0.77 mag (a factor of two drop in accretion luminosity) requires a fall in the accretion rate by at least a factor of two, and this forces an increase in the inter-eruption time interval. The long delay since 1967 was simply because the rate of accumulation on the white dwarf surface had at least halved.

With the prediction from Schaefer (2005) that the next eruption was a long way in the future, professional preparations for the next eruption (like the long-running Target of Opportunity program with the *Hubble Space Telescope*) were stopped. But this did not deter many amateur observers (who were generally fully aware of the prediction) from continuing to regularly check for eruptions, report visual magnitudes, and make long photometric time series with CCDs. For example, Stubbings started in early 1998 in making 2004 visual estimates of the brightness of T Pyx with a 16-inch reflecting telescope in Victoria Australia, while Richards made CCD time series observations on five nights in early 2008 with 661 brightness measures.

From 2008 until 31 March 2011 (JD 2455652), T Pyx held at a steady magnitude of V=15.5, with the usual periodic variations of $\lesssim$0.2 mag. For the 610 observations in the last 4000 days of this interval, Stubbings never saw T Pyx brighter than V=15.0. Thus, it was a distinct surprise when Stubbings saw T Pyx at V=14.5 on JD2455657.0104 (UT 2011 April 5.51), with the realization that this could be an initial rise of the next T Pyx eruption. With this exciting possibility, Stubbings checked T Pyx five more times before dawn, but saw only variations from 14.4 to 14.7. On the next night T Pyx was slightly fainter, and it continued a slow fade until JD2455662.0417 (UT 2011 April 10.54). The light curve just before the sharp rise to the eruption (see Figure 1) shows a significant short-duration pre-eruption rise, which started roughly 13 days before the eruption, peaked at around V=14.4 mag (close to 1.1 mag above the prior quiescent level), and declined towards quiescence before the eruption.

The existence of this pre-eruption rise has been confirmed with the archival data from the *All Sky Automated Survey* telescope located at the Las Campanas Observatory in northern Chile (Pojmanski 2002). The images were taken through a Bessel V filter and magnitudes are tied to a large number of comparison stars in the field with magnitudes in the Tycho catalog. This procedure can lead to moderate offsets for an object with unusual color (like T Pyx), and indeed the average magnitude in the year before eruption (15.12) is brighter than the average of other V-band measures (V=15.51) over the same time interval. Nevertheless, the differential photometry is excellent to within the statistical uncertainties (typically 0.09 mag). For the year prior to JD 2455654.5972, T Pyx was seen to vary about its average with an RMS scatter of 0.14 mag. On JD 2455656.62097 (0.4 days before Stubbings discovery of the rise), T Pyx was 0.43 mag brighter than the average, with this being the brightest magnitude by far in the prior year. This is the confirmation of the pre-eruption rise. On JD 2455658.62564 and 2455660.62294, T Pyx was consistent with being back to the prior average. Thus, the apparent duration of the pre-eruption rise is roughly four days with the beginning around 11 days before the start of the eruption.

This pre-eruption event is one of an unusual phenomena that is still completely mysterious. Collazzi et al. (2009) report an extensive survey of archival data for 22 novae with well-sampled pre-eruption light curves, which showed that two of these (V1500 Cyg and V533 Her) have pre-eruption rises with different time scales and morphology, while one nova (T CrB) has a significant pre-eruption dip. Table 1 summarizes the properties of these events. In all cases, the pre-eruption rise cannot be some early part of the usual thermonuclear runaway because the anticipation times and the durations (weeks and years) are greatly longer than both the theoretical runaway timescale (hours) and the observed rise times (hours).

In all cases, the pre-eruption event is highly significant and unprecedented for long time intervals before the eruptions and after the eruptions. For example, the dip before the 1946 eruption of T CrB was deepest (by roughly 2 magnitudes below the usual quiescent level) just 29 days before the eruption, whereas there are no other dips from 1867 to 1945 and from 1947 to 2011. The uniqueness and the time coincidence immediately before the eruption provide proof of a causal connection. It is difficult to understand this connection, because the pre-eruption brightness level is dominated by the accretion which is governed by the mass falling off the donor star, while the timing of the eruption is governed by conditions at the bottom of the accretion layer deep under the surface of the white dwarf. How could the donor star near the L1 point possibly *anticipate* that conditions deep in the white dwarf will soon heat to the trigger threshold? We can only speculatively invent several possibilities. Perhaps some isotope within the accreted layer starts burning so as to heat the bottom of the layer up to the point where the thermonuclear runaway can start, but we do not see how the very small heated surface of the white dwarf can significantly brighten the whole system, nor do we know any suitable isotope. Perhaps some random increase in the accretion rate will heat up the accretion layer sufficiently so as to trigger the thermonuclear runaway, but the pre-eruption increases are so unique (especially that of V1500 Cyg) that it seems they are not from any independent original cause, the extra energy of accretion is too small to make any significant rise in temperature at the base of the layer, and the accretion energy cannot get to the bottom of the layer on the time scale of days as required for T Pyx. In all, we can think of no plausible explanation for the pre-eruption rises, while the pre-eruption dip for T CrB does not even have these poor speculations to explain why its turn-off of accretion anticipated its eruption. We regard the explanation of these pre-eruption phenomena as a premier challenge for nova theory.

Linnolt had also been monitoring T Pyx since March 2009 from Hawaii, waiting for an eruption, as part of a larger program of monitoring recurrent novae for eruptions (e.g., Schaefer et al. 2010b). He used a 20-inch aperture Newtonian reflector telescope operating visually at 500x magnification, so that observations down to V=17 were possible. On JD2455664.8590 (UT 2011 April 13.36), Linnolt observed T Pyx at V=14.5 and realized that this was unusually bright, and hence a possible indication of an eruption. With anticipation, Linnolt checked T Pyx early the next night (JD2455665.7931, UT 2011 April 14.29), saw that the star was bright (V=13.0), and immediately realized that an eruption had started. Within 15 minutes, the discovery was announced on the AAVSO discussion group which is closely monitored by interested amateurs and professionals worldwide. The discovery was quickly confirmed by Australian visual observers Plummer (JD2455665.8847 V=12.2) and Kerr (JD2455665.941 V=11.3). CCD observers Nelson, Carstens, and Streamer started taking time series photometry in multiple bands by JD2455665.9973.

To the best of our knowledge (e.g., Payne-Gaposchkin 1964; Robinson 1975; Collazzi et al. 2009; Strope, Schaefer, & Henden 2010; Schaefer 2010), the 2011 eruption of T Pyx has by far the best observed initial rise from quiescence. Only a handful of old novae have had just a few points taken during the later half of their initial fast rise, whereas T Pyx has high time resolution time series with near full-time coverage and in multiple bands. Indeed, T Pyx is the only nova with any observations in the middle or the first part of the initial fast rise. The very fast alert to the world and the very fast reaction by observers worldwide made this possible.

3. The 44 Year Inter-Eruption Interval

Schaefer (2005) and Schaefer et al. (2010a) made a quantitative physics-based prediction that the date of the next T Pyx eruption would be in the year 2052 or much later. The first key idea is that the accretion rate (and hence the accumulation rate on the white dwarf) can be measured from the blue flux, so a B-band light curve between eruptions can be used to determine the average accretion rate. The general relation will be

$$\dot{M} = \dot{M}_{16} F_B^E = \dot{M}_{16} 10^{-0.4E(B-16)}, \tag{1}$$

where $\dot{M}$ is the accretion rate, $\dot{M}_{16}$ is the accretion rate when T Pyx has a B magnitude of 16.0, B is the B-band magnitude, F_B is the B-band flux in units of the the flux when B=16, and E an exponent expressing the physics of the light sources in T Pyx. The use of the B=16 mag level is arbitrary (any other magnitude level could have been adopted), but this choice is convenient for T Pyx. The second key idea is that the total mass accreted between eruptions can be estimated from the accretion rate averaged over the inter-eruption interval of ΔT, with

$$\Delta M_{acc} = \langle \dot{M} \rangle \Delta T. \tag{2}$$

Here, the accretion rate values from equation 1 are averaged over all available blue magnitudes. The third key idea is that the trigger mass will be close to the mass accreted between eruptions:

$$M_{trigger} = \Delta M_{acc}. \tag{3}$$

The fourth key idea is that a given recurrent nova system should have a unique trigger mass that will be the same for all eruptions. The trigger mass can only be a function of the white dwarf mass, radius, magnetic field, and the composition of the accreted material, and these vary from RN to RN, but not from eruption to eruption. This can be expressed as

$$M_{trigger1} = M_{trigger2} = M_{trigger3} = \ldots, \tag{4}$$

where the numerical subscript indicates different eruptions. Putting these equations together, we see that $\langle F_B^E \rangle \Delta T$ should be a constant from eruption to eruption. For intervals where the RN is bright on average, then the accretion rate will be high, the trigger mass will be accumulated relatively fast, and the inter-eruption interval will be relatively short. For intervals where the RN is faint on average, the time between eruptions will be long. For both T Pyx and U Sco (Schaefer 2005; Schaefer et al. 2010b), the blue flux was seen to vary with the short inter-eruption intervals having a bright quiescence (and thus a high accretion rate) and with the long inter-eruption intervals having a faint quiescence (and thus a low accretion rate). We now can determine the current inter-eruption time interval as

$$\Delta T_3 = \Delta T_2 \langle 10^{-0.4E(B-16)} \rangle_2 / \langle 10^{-0.4E(B-16)} \rangle_3. \tag{5}$$

The subscripts on the brackets indicate an average over the indicated inter-eruption interval.

We now have a means of predicting the date of the next eruption by simply measuring the historical light curve along with some assumption for the continuing brightness. By calibrating with previous inter-eruption intervals, the various constants of proportionality cancel out, and we need never know the trigger mass, accretion rate, or the distance. Schaefer (2005) predicted that the next eruption of U Sco would be in 2009.3±1.0, and this formed the basis for a large international collaboration of researchers at all wavelengths designed to discover and then intensively observe the eruption. With the discovery of the eruption in 2010.1 by B. Harris and S. Dvorak, this advance preparation allowed the U Sco eruption to become the all-time best observed nova event. Schaefer (2005) also predicted that T Pyx would next erupt in 2052±3, while Schaefer et al. (2010a) extended this date to the year 2225 or much later.

This prediction for T Pyx was refuted by the 2011 eruption. So the task now is to understand *why* the prediction went so far wrong. The basic logic of the prediction is simple and easy. The light curve is confident and the mass for the trigger threshold really has to be constant. About the only place that could be wrong is the conversion from the B-band magnitude to an accretion rate. Schaefer (2005) calculated that the accretion rate is proportional to the blue flux raised to the 2.0 power (i.e., $E = 2$), with this exponent being derived from a model for a simple accretion disk with the parameters for T Pyx. (For U Sco with its much larger disk, the exponent is 1.5.) So this exponent is the likely cause of the wrong prediction.

If the exponent is around 1.0, then the predicted date would have been reasonably close. This is the case where the accretion rate is simply proportional to the B-band flux. The quiescent magnitude from 1944 to 1967 was 14.72, while from 1967 to 2005 it was 15.49 (Schaefer 2005), for a magnitude difference of 0.77 mag, corresponding to a ratio of B-band flux of close to 2.0. For the accretion rate being proportional to the B-band flux, the average accretion rate must then also have a ratio of close to a factor of 2.0, and the post-1967 interval must be 2.0 times that of the pre-1967 interval. This would imply an eruption 2.0×22 years after 1967, which predicts the next eruption in 2011. So it seems that, somehow, T Pyx effectively has the B-band flux being proportional to the accretion rate (i.e., $E \approx 1$).

This fast and easy analysis can be substantially improved. Using the quiescent light curve and the inter-eruption time intervals, the value of E that makes for the most constant $\langle F_B^E \rangle \Delta T$ from interval to interval can be found.

To this end, we have accumulated a large number of magnitudes of T Pyx in quiescence. Table 2 presents these magnitudes, although the collected limits and visual estimates are not included. (The printed table only shows only the first 10 lines for illustration, while the full table is available in the electronic paper.) The total is 6114 magnitudes, including 3856 magnitudes during quiescence from 1890-2011, 15 magnitudes during the pre-eruption rise just before the 2011 eruption, and 2243 magnitudes in the first two days of the 2011 eruption. Figure 58 of Schaefer (2010) already displays most of the B-band magnitudes, showing the secular decline since 1890. The magnitudes before 1954 are all from the Harvard College Observatory plate archives and are tabulated here for the first time. After the 1967 eruption, magnitudes were reported by Mumford (1971), Landolt (1970; 1977), Schaefer et al. (1992), and Patterson et al. (1998). We also report many more magnitudes for the first time, including many individual nights from 1987-2009 with BVRI photometry with various telescopes at Cerro Tololo Inter-American Observatory by Schaefer, time series on five nights in 2008 at Pretty Hill Observatory by Richards, time series on three nights in 2011 in Huntington California by Myers, and time series on five nights in 2011 at Ellinbank Observatory by Nelson. The time series in 2011 were made in support of observations by the *Chandra* X-ray observatory. By good fortune, these time series were as close as 48 days before the eruption, and this is critical for getting an accurate pre-eruption orbital period. We have collected more unpublished magnitudes that are recorded in the AAVSO database. Many more magnitudes in quiescence are already known (mainly in the large database of the *Center for Backyard Astronomy* as reported in Patterson et al. 1998 and Uthas et al. 2011) and can be measured (mainly with the archival plates from the 1920's to the 1980's at the Sonneberg Observatory), with these extra magnitudes able to fill some of the gaps in time.

To determine the best fit exponent, we have taken the B and V magnitudes from each of the intervals. (The R and I magnitudes are few in number and usually nearly simultaneous with a B and V magnitude.) The V magnitudes are converted to B magnitudes by using the long term average of $B - V = +0.12$ (Schaefer 2010). Nightly averages are formed, so that a few nights with many magnitudes as part of a time series (which might or might not be representative of the whole interval) do not dominate the average. The B-band magnitudes are then converted to flux with Equation 1, where E is held as a free parameter. These nightly averages are then straight averaged for each inter-eruption time interval. The uncertainty is taken to be the RMS scatter divided by the square root of the number of nights. (If the nightly averages are first formed into yearly averages and these are averaged, then we get fluxes which are essentially identical.) Table 3 gives the pre-eruption intervals, their durations (ΔT from Schaefer 2010), the average B-band magnitudes over each interval ($\langle B \rangle$), the average F_B for those intervals, the values of $\langle F_B \rangle \Delta T$ (which should be nearly constant), and the values of $\langle F_B^{1.13} \rangle \Delta T$.

The only free parameter in this analysis is E. The best estimate for E will be that value which returns the most constant values for $\langle F_B^E \rangle \Delta T$ across all measured time intervals. The values and the scatter will scale as E changes, so we find the value of E that has the least fractional scatter. The smallest fractional scatter is near $E = 1.13$, with 13% RMS variations across the five intervals with measures. With this, Table 3 has the value of $\langle F_B^{1.13} \rangle \Delta T$ in the last column, with a straight average of 71. Table 3 also lists the values of $\langle F_B \rangle \Delta T$ (with a straight average of 64) because later we will provide a theoretical justification that $E = 1$.

The scatter in $\langle F_B^E \rangle \Delta T$ is much larger than the formal uncertainties, and this indicates that our basic model is not exact. So, at the 13% level, the imperfect sampling of the light curve might be misrepresentative, the value of E varies, or the trigger mass might vary from eruption to eruption. For whatever reason, this means that the total uncertainty in $\langle F_B^E \rangle \Delta T$ is around 13%, so for five independent measures the uncertainty on the average is around 6%. For predicting any single inter-eruption interval, the uncertainty will be 13%. Adopting a 13% uncertainty, we can make a chi-square fit for E, with this giving a value of 1.13 ± 0.14. As such, we see that the five inter-eruption time intervals are consistent with $E = 1$.

The observed inter-eruption intervals and light curves are consistent with $E = 1.13 \pm 0.14$, but we still need to explain the low E value. For this, the basic calculation of Schaefer (2005) was repeated with various physically motivated differences. The basic model adopted the usual thin α-disk, extending from near the surface of the white dwarf to 90% of the Roche lobe radius, with the ordinary disk light (expressed in Equations 5.45 and 5.49 of Frank et al. 2002) dominating the system. New shows that T Pyx is an intermediate polar and that this is driving bright continuing nuclear burning on the surface of the white dwarf (Schaefer & Collazzi 2010). We know that T Pyx is an intermediate polar because it displays the typical unstable photometric periodicities near the orbital period (Patterson et al. 1998), with this being the observational hallmark of intermediate polars. This new evidence means that the disk is truncated by the magnetic field, with an inner edge far from the white dwarf, and the disk might be only a small annulus or there might not even be any recognizable disk. This also means that T Pyx has a bright supersoft X-ray source on the white dwarf that is irradiating the disk, accretion column, and companion star, hence contributing substantial luminosity that is reprocessed into the B-band. This supersoft source hs faded over the last century, with its luminosity falling as the accretion rate falls. So we now have two modifications to the basic model (truncated disks and reprocessing of the supersoft light) that might change the theoretical value of E.

To evaluate the exponent E in $\dot{M} \propto F_B^E$ for the relevant conditions, hte system brightness as a function of the accretion is calculated. The luminosity of the supersoft source will be $0.007X\dot{M}c^2$ for hydrogen burning, with X being the hydrogen fraction taken to be the solar value of 0.7. The temperature of the reprocessed light is given by Equation 5.93 of Frank et al. (2002). The blue flux from the disk comes from the sum of the blackbody brightness of each annular ring throughout the disk with the temperature varying with radius. With this, we confirm that $E \approx 2$ for the case with no reprocessing and no truncated disk. This exponent can be varied somewhat with the accretion rate, but even with a low accretion rate of 1×10^{-8} $M_{\odot}$ yr^{-1} E is still 1.82. Further, we find the same result with varying inner disk radius and reprocessing sites. That is, $E \approx 2$ is still the best model value. The lowest exponents come from the inclusion of reprocessing off the companion star, the largest radii of the inner edge of the disk, and lowest accretion rates, but we never get $E < 1.5$ for any plausible conditions. A further problem with these extreme conditions is that the total luminosity from the system becomes much fainter than observed, even if the distance to T Pyx is as close as possible. Under no plausible conditions can we get E approaching unity. That is, our more complicated and realistic models cannot account for the $E = 1.13 \pm 0.14$ value required to explain an eruption in 2011.

We can understand this general result with a simple argument. First we have the luminosity of all the various components in the system being proportional to the accretion rate ($L \propto \dot{M}$). This includes the luminosity from viscous heating in the disk, the accretion column, the supersoft source, and all the reprocessed light that is proportional to the white dwarf luminosity. (This is not exact, as the disk and the reprocessed light are also proportional to the disk height which scales as $\dot{M}^{0.15}$. Importantly, all the light sources in the system that are nearly constant, like the unheated companion star and the white dwarf itself, are negligibly faint.) Second, all of the significant light sources in the system have luminosity coming from blackbody emission, or as the sum of blackbodies with a range of temperatures, for which $L \propto \sigma T^4$. Third, for the case of relatively hot blackbodies, we are near the Rayleigh-Jeans limit for which $F_B \propto T$. Putting these three scaling laws together, we get $\dot{M} \propto F_B^4$, which is to say $E = 4$. Even with the scaling with disk height, we only get $E = 4/1.15 = 3.5$. In reality, the emitting objects are not so hot as to have the blue light being far out on the Rayleigh-Jeans tail, so F_B becomes proportional to a higher power of T and E lowers to around 2. The temperatures predicted in the T Pyx system are all relatively high because the system has a very high accretion rate, the supersoft source is powered by nuclear burning, and the system is small as indicated by the short orbital period. (In contrast, most other cataclysmic variables have much cooler emission from the accreting material because they have greatly lower accretion rates, a white dwarf whose luminosity is powered only by accretion, and a larger disk with cooler outer parts.) So we have a general conclusion that blackbody emission from all the bright system components have $E \sim 2$ and certainly nowhere near $E \sim 1$.

This general conclusion does not apply if the dominant light source does not emit as a blackbody. At first look, a good reason to take the system light to be from a thermal disk is that its spectral energy distribution is a rising power law reminiscent of the $F_\nu \propto \nu^{1/3}$ that is characteristic of accretion disks (Schaefer 2010). But this simple argument fails because the power law stretches from K-band to U-band, and this requires a much broader thermal disk than is possible for T Pyx. To get a $\nu^{1/3}$ spectral region stretching over almost an order of magnitude in frequency from a thermal disk requires that the radius of the outer edge of the disk be more than a thousand times the radius of the inner edge (see Figure 5.2 of Frank et al. 2002). This cannot be the case for T Pyx because the outer edge is truncated by the Roche lobe ($10^{10.5}$ cm) while the inner edge is truncated by the white dwarf ($10^{8.8}$ cm) and the magnetic field (10^9 cm to nearly $10^{10.5}$ cm). On looking closer, the rising power law is $F_\nu \propto \nu^{0.9}$ (Gilmozzi & Selvelli 2007; Schaefer 2010), which is substantially bluer than any known thermal disk in a cataclysmic variable. (A small portion of a blackbody spectrum can have such a slope, but not over the large range from the infrared to ultraviolet.) This is emphasized by the incredibly blue U-B color of -0.95 (Mumford 1971; Landolt 1970; 1977) or -1.25 after reddening correction (Webbink et al. 1987). (Indeed, we have just recognized that the U-V color for T Pyx had been incorrectly transferred from Table 25 to Table 32 of Schaefer 2010 without the negative sign, and so the spectral energy distribution in Figures 70 and 71 show a false turn down in the ultraviolet. Actually, when done correctly, the placement of the U-band point is in line with the rest of the power law shape.) The overall shape of the T Pyx spectral energy distribution has no precedents among cataclysmic variables or related objects (Dubus et al. 2004; Harrison & Gehrz 1992). Thus, the light from T Pyx is not from a thermal disk (with or without any of the effects like reprocessing) because its spectral energy distribution is unlike any other cataclysmic variable disk and because the observed power law has a range in wavelength that implies a very large span of disk radii that is impossible for T Pyx.

The spectral shape is not possible for any blackbody (or sum of blackbodies) within the Roche lobe of the white dwarf. The problem is that the spectrum shows no sign of turning over to a Rayleigh-Jeans slope ($F_\nu \propto \nu^2$) even far out into the infrared, and this makes it impossible to produce the optical and infrared flux from any combination of blackbodies within the Roche lobe. The calculated K-band brightness for a uniform blackbody with the radius of the Roche lobe and a temperature of 1350 K (to place the spectral peak in the K-band) is 23.8 mag, as opposed to the observed K=14.18 (Schaefer 2010). We can match the observed brightness only with an emitting surface area roughly 7000 times larger than the Roche lobe. If we try adding in a hotter blackbody, then we should start to see the Rayleigh-Jeans tail. For a 3000 K blackbody (to have the Wien peak at 965 nm so that the Rayleigh-Jeans tail should be readily visible in the K-band) from the surface area of the Roche lobe, we get K=20.8, which is still several hundred times too faint to explain the observed flux. If we add in a 34,000 K blackbody with the size of the Roche lobe, then we still get only K=16.9. (An effective temperature of 34,000 K has been suggested to account for the observed ultraviolet spectrum by Gilmozzi & Selvelli 2007.) The addition of hot blackbodies then results in a mismatch with observations because the required Rayleigh-Jeans tail is not seen. No possible combination of blackbodies within the Roche lobe can reproduce the observed infrared flux. Even in the R-band, the observed flux cannot be accounted for by a blackbody any cooler than 34,000 K, and this is rejected by the utter lack of a Rayleigh-Jeans tail in the spectral energy distribution. The B-band flux can be produced by a 34,000 K blackbody from a region about half the size of the Roche lobe, but again this possibility is rejected by the lack of a Rayleigh-Jeans tail. The addition of blackbody flux from a hotter region would not solve the problem, while the addition of blackbody flux from a colder region could never add significant flux to hide the Rayleigh-Jeans tail. In all, the observed spectral energy distribution from the K-band to the B-band cannot arise from a blackbody (or sum of blackbodies) from within the Roche lobe.

So where does the optical and infrared light come from? One possibility is that the light comes from a circumbinary disk. Such a disk could form from material ejected during the accretion process, and this material could be quite massive. Any such disk must reside substantially further away from the white dwarf than the companion star, and hence its material must be relatively cold. This could easily account for the infrared flux. Any such disk should be blown away during each recurrent nova eruption, so a test of this circumbinary disk possibility will be to look for the infrared flux after the 2011 eruption has completely stopped. However, for any plausible temperature, the circumbinary disk cannot account for the B-band flux. The only other possibility is that the optical light is from nonthermal emission, which is to say from neither optically thick sources nor blackbody sources. Possible mechanisms for the optical continuum include cyclotron, bremsstrahlung, and Thompson scattering of some interior light. So we conclude that the optical continuum from T Pyx must be dominated by some nonthermal emission mechanism, while the infrared light might be dominated by some circumbinary disk.

If the optical light cannot be dominated by blackbodies, then the earlier models (with

$E \approx 2$) all become irrelevant. There are three reasons why the usual α-disk models won't work for T Pyx. First, T Pyx is an intermediate polar so high magnetic fields will destroy much of the thermal disk structure and allow for cyclotron radiation. Second, thermonuclear burning might still be occurring on the surface of the white dwarf, and this emission will dominate any disk, with this being rare among cataclysmic variables. Third, T Pyx has a very high accretion rate, as it must have to be recurrent, with the local accretion rate on the pole caps of the white dwarf leading to unusual configurations (Nomoto 1982), with this being rare among cataclysmic variables. T Pyx exhibits all three conditions and thus comparison with cataclysmic variables has limited relevance. T Pyx has high luminosities and magnetic fields, conditions which favor nonthermal emission. Indeed, the spectral energy distribution shows that the optical light is dominated by non-thermal, rather than thermal, emissions.

Nonthermal emission must be optically thin. In various plausible situations, the emitted flux will be proportional to the accretion rate. For example, for cyclotron radiation in an optically thin region, the flux will be proportional to the number of electrons, which will be proportional to the accretion rate, so that E=1. Or if the geometric volume of the emission region scales as the accretion rate (for example, a doubling of the rate leading to a doubling of the volume), then even emission by bremsstrahlung (which scales as the square of the electron density) will yield E=1. Or if the thermal energy of the electrons in the optically thin region is controlled by the luminosity of some underlying optically thick region that is proportional to the accretion rate, then the flux from cyclotron is proportional to the electron thermal energy and hence to the accretion rate, so that E=1.

So we now have a plausible explanation for why T Pyx erupted in 2011. The observed flux from T Pyx has been declining for the last 121 years, so the accretion rate has been falling and it takes longer times between eruptions to accumulate the nova trigger mass. In the 22 year inter-eruption interval before the 1967 event, T Pyx was nearly a factor of two times brighter on average compared to the next inter-eruption interval, so the next inter-eruption interval should be roughly twice as long (i.e., around 44 years). Therefore, the next eruption after 1967 should occur in 1967+44, which is to say in the year 2011. A more accurate postdiction is to use the average value of $\langle F_B \rangle \Delta T = 64 \pm 9$ and $\langle F_B \rangle = 1.47 \pm 0.011$ to get $\Delta T = 43.6 \pm 5.9$, which puts the eruption peak in 2010.7±5.9. The uncertainty on this postdicted date is not small, so the close coincidence between the postdiction and the real eruption date is fairly surprising.

The error in the Schaefer (2005) and Schaefer et al. (2010a) predictions is simply the standard assumption that the light was being dominated by the usual thin α-disk (which yields $E \approx 2$). With the realization that the T Pyx light must be nonthermal and optically thin, we can get $E = 1$ and an expected eruption around the year 2011.

4. The Orbital Period Before Eruption

In the classic review of RNe, Webbink et al. (1987) concluded that T Pyx must have a relatively short orbital period (like those of the typical classical novae) due to the lack of any red excess. Early photometric periods suggested were 0.069 days (Szkody & Feinswog 1988) and 0.1433 days (Barrera & Vogt 1989). With a much larger set of time series photometry, Schaefer (1990) found a stable and highly significant modulation but had severe daily alias problems, for which the highest peak in the Fourier transform was at 0.099 days, while another lower peak was at 0.076 days. Schaefer et al. (1992) collected an even larger set of time series from 1966 to 1990 and determined the period to be 0.07616±0.00017 days. Patterson et al. (1998) made long runs from 1996 to 1997 to confirm this orbital period, discovered a steady period change, and discovered a complicated structure of weaker periodicities that vary in amplitude. Uthas et al. (2011) demonstrated that the stable 0.076 day photometric period equals the orbital period as measured with a radial velocity curve. They also used many minimum timings from 1996-2009 (from the records of the *Center for Backyard Astronomy*) to give a high precision ephemeris that includes a parabolic term. This gives the minima times as

$$HJD = 2451651.65255 + 0.076227249N + 2.546 \times 10^{-11}N^2, \tag{6}$$

where N is the number of orbital cycles from the epoch.

A highly accurate pre-eruption orbital period, together with a post-eruption period, will give the change in orbital period across the 2011 eruption. This period change will then give the ejected mass with high accuracy and no need for uncertain quantities (like the distance) or dubious assumptions (like the shell filling factors). For the case of T Pyx (but not for the other RNe), the dynamical friction of the companion star within the nova envelope will also cause a small period change (Livio 1991; Schaefer et al. 2010a) and this effect must also be taken into account. The ejected mass is critical for knowing whether the RN white dwarf is gaining or losing mass over the eruption cycle, and hence whether the RN will soon become a Type Ia supernova. Previously, only two other RNe (U Sco and CI Aql) had a measure of the period change across the eruption (Schaefer 2011). The T Pyx eruption of 2011 provides an opportunity to measure the period change for a third RN.

As the period of T Pyx changes, it is vital to determine the pre-eruption orbital period for the time immediately preceding the eruption. To good accuracy, Equation 6 should work well to give the pre-eruption orbital period. With this, for an epoch of N=52662, the pre-eruption orbital period is 0.07622993±0.00000017 days. However, this period is based on minima times only until 2009. However, we also have the time series in February 2011, up to 48 days before the eruption. The possible existence of small period changes just before the eruption is critical where we need part-per-million accuracy. In this section, we will test the ephemeris of Uthas et al. (2011) and extend it from 2008 to February 2011 so as to get the period immediately before the eruption.

With the time series photometry in Table 1, we have performed chi-square fits of the folded light curve to a template. The folded light curve is folded around the period from the parabolic ephemeris of Equation 6. (We are dealing with time series of such short length that any approximate period would have been adequate.) The template we used was a flat light curve from phases 0.25-0.75 with a linear and symmetric decline to a minimum at zero phase of 0.15 mag fainter (see Figure 10 of Patterson et al. 1998). This procedure yields a formal uncertainty on the time of minimum, but this only accounts for the measurement errors. The uncertainty is actually dominated by the orbit to orbit variations in the light curve (see Figure 54 of Schaefer 2010 and Figure 8 of Patterson et al. 1998) caused by the usual flickering plus other unstable periodicities. When one orbit is considered, the light curve occasionally does not have an obvious minimum. However, when many orbits are considered together, the combined light curve always looks similar to the template. So the accuracy of the times of minima should scale as the inverse square root of the total duration of data in the time series in terms of the orbital period. For a group of similar observations over a relatively small time range, the scale of this uncertainty can be set by looking at the scatter in the O-C curve about some smooth best fit line. So for example, the uncertainty in the minimum times reported by Patterson et al. (1998) can be calculated as $0.0033(\Delta/0.076)^{-0.5}$ days, with Δ being the total duration of the observation (not necessarily contiguous) in days. With this, Table 4 presents the available times of minimum (in heliocentric Julian days) with their uncertainties. Included are six times of minimum from Patterson et al. (1998).

These minima times can be compared to a linear ephemeris by means of the O-C diagram. For the linear predictions, we merely take Equation 10 while zeroing out the quadratic term. For each minimum time, we calculate the number of cycles from the epoch (to the nearest integer), use equation 6 (without the quadratic term in this case) to calculate the model time, then difference this time from the observed time to form the usual O-C curve. The O-C values for the linear ephemeris are presented in Figure 2 as a function of the year. Uthas et al. (2011) reports that they have a large number of additional minimum times from 1998-2009, and these can well fill the gap in the O-C curve. We see a nicely shaped parabola, which fits well with Equation 6.

We have also sought deviations from the parabolic ephemeris. For this, we constructed another O-C curve where the ephemeris was Equation 6 (see the lower panel of Figure 2). If the Uthas et al. (2011) model is perfect, then all the observed minimum times should lie along the horizontal axis with $O - C = 0$ to within the plotted error bars. Indeed, we see that the early time series from Schaefer et al. (1992), Patterson et al. (1998), and from early 2008 by Richards all fall close to the axis. This is to say that the parabolic ephemeris is a good match to the observed times from 1988-2008. The two times in 1986 and 1987 are roughly 2-sigma and 1-sigma above the line, with a weak suggestion of deviation from Equation 10 before 1988, although we judge this suggestion to be too weak to accept. However, the two times from February 2011 are both closely consistent and with 3.7-sigma and 5.1-sigma deviations from the parabolic ephemeris. These two measures indicate that T Pyx underwent a very small but significant change in period from 2008 to 2011. If the O-C curve is linear from 2008 to 2011, then the orbital period at the time of the eruption was 0.07622916±0.00000008 days.

This result is encouraging, since the period has an accuracy of one part per million, which is in the right range to see the expected period change. However, this result is discouraging because it is 10 parts-per-million different from Equation 6. So it appears that the dominant uncertainty will likely be from very small changes in the orbital period, not from measurement errors.

How long will it take to get a part-per-million post-eruption orbital period? With one full night of time series, the uncertainty in the minimum time should be roughly 0.0015 days. With two such observations separated by six years (with ∼29,000 cycles), the uncertainty in the derived period will be close to one part-per-million. This duration can be improved by having more than just the two measures, with this improvement scaling as the square root of the number of minimum times. Over a three year interval, we could still get a part-per-million accuracy with eight full nights of photometry.

5. The Rise to Peak

T Pyx has a well-defined light curve with essentially continuous coverage and BVI colors starting at the the time of the discovery (Figure 3 and Table 2). The nova rose from V=13.0 (discovery) to V=10.0 in a time of 8 hours, for an average rate of 9.0 mag day^{-1}. This fast rise slows within the first day, rising to V=7.9, 2.0 days after discovery. Then, T Pyx fades by a third of a magnitude over the next day, followed by a very slow rise back to V=7.9 over the next five days. Soon after this, the rise increases to a minor peak of V=6.7 on JD2455685 (19 days after discovery) and then up to the highest peak of V=6.4 on JD2455693 (27 days after discovery).

We have measured the colors of the initial rise of a nova eruption (see Table 2). The B-V curve is plotted in Figure 4. We see that the first measures (when T Pyx was around eleventh magnitude) have median $B-V=-0.02$, but this slowly changes to $B-V=+0.23$ by two days after the start. At this time, just as the light curve is nearly flat, the $B-V$ color curve also goes nearly flat. Just after discovery (around JD2455666.07), the median colors are $B-V=-0.02$ and $V-I=+0.39$. These colors are inconsistent with a blackbody, as for example an A0 star with a temperature near 10,000K ($B-V=0.00$) has the V-I color equal to 0.00, which is substantially different than that seen in T Pyx. Half a day after discovery (JD2455666.65), the median colors are $B-V=+0.06$, $V-R=+0.27$, and $V-I=+0.37$. At the time when the fast initial rise breaks (JD2455668.0), the median colors are $B-V=+0.23$ and $V-I=+0.58$.

The initial rise of a nova can be simply modeled by a uniformly expanding shell. The observed flux from the system will equal

$$F = F_0 + (v\tau/D)^2 F_\nu(T). \tag{7}$$

Here, F_0 is some constant flux from the disk and companion star, v is the expansion velocity of the outer edge of the shell (corresponding to the effective photosphere), τ is the time of expansion, D is the distance to the T Pyx system, T is the effective temperature of the photosphere, and $F_\nu(T)$ is the flux from a unit area of the photosphere. For the case of bolometric flux, $F_\nu(T)=\sigma T^4$ for a blackbody photosphere. Equation 7 can be converted into AB magnitudes as

$$m = -48.60 - 2.5\log_{10}[F_0 + C(t-t_0)], \tag{8}$$

with

$$C = (v/D)^2 F_\nu(T). \tag{9}$$

Here, τ is expressed in the more practical form of the time (t) minus some fitted zero time for the start of the rise (t_0). C is a combination of values that presumably remain nearly constant throughout the fast initial rise. Before t_0, the magnitude should be a constant corresponding to the flux F_0 alone. We now have a simple model with three unknowns (F_0, C, and t_0) that should describe the initial rise.

We have fitted our T Pyx light curve from the time of discovery until JD2455668.0 with a chi-square analysis. This includes 2151 magnitudes. To get a reduced chi-square of unity, we had to adopt a systematic uncertainty of 0.25 mag, which is a measure of systematic errors in the measurements plus deviations from the model. Our best fit model is shown in Figure 3. The constant flux corresponds to a magnitude of 14.63, $t_0 = 2455665.967$, and $C = 1.56\times10^{-23}$ erg s^{-2} cm^{-2} Hz^{-1}. This model fits the initial fast rise well, and gives some confidence that the simple model is close to the real case. The sudden deviation two days after the initial rise would then indicate some significant departure from the simple model in the sense that the expanding shell appears fainter than expected. We suggest that this deviation is caused by the outer portion of the ejecta expanding to become optically thin enough so that the photosphere can shrink significantly in size.

We had originally hoped that this rise could be used to determine an accurate distance to T Pyx by the Baade-Wesselink method. (The distance to T Pyx is poorly known, for example with Schaefer (2010) giving 2500-4500 kpc.) Our light curve fit gives a value for C, the spectral line widths will give V, and we can use theory or colors to estimate $F_\nu(T)$). Then the distance can be directly derived from Equation 9. Unfortunately, the inputs are known only poorly. For the velocity, we do not know what position in a line profile (e.g., half-width-zero-intensity or half-width-half-maximum) corresponds to the velocity at the photosphere. For $F_\nu(T)$, the blackbody approximation is expected to be good for the photosphere, but the early colors are inconsistent with a blackbody. As such, the temperature cannot be determined with any useful confidence from observation of the colors. Also, no early spectrum exists so that we cannot get the temperature from spectral lines. From theory, the temperature varies by a factor of $\sim$3, with a strong dependance on the white dwarf mass and other model details. With no way to get the temperature to any useful accuracy, we cannot get $F_\nu(T)$ even if we know the emission mechanism. Nor can we turn this around to derive $F_\nu(T)$ from C, D, and V, because again the uncertainties of the inputs would be too large to be useful. In all, even though C is fairly well measured, we cannot get useful information on any of D, V, or $F_\nu(T)$.

6. Accretion Rate

We can use our data and analysis to address the question of the quiescent accretion rate. The value of $\dot{M}$ is key for understanding a variety of peculiarities in the T Pyx system. Perhaps the most critical question is reconciling the necessarily high accretion rate with the low X-ray luminosity. Here are four methods for determining $\dot{M}$, some new, some old, and some failing.

Method 1: The orbital period of T Pyx has been changing closely linearly with time (see the good parabolic shape of the O-C curve in Figure 2). This large and steady period change can only arise from the mass transfer in the system. (Being below the period gap, T Pyx will not suffer from significant angular momentum losses from magnetic breaking, which can only make the period decrease.) The observed increase in the orbital period is expected when a low mass donor star transfers matter to the high mass white dwarf. The period change will be proportional to $\dot{M}$, so we can use the observed period change to deduce the accretion rate. The default scenario is conservative mass transfer, in which all the mass leaving the donor star arrives onto the white dwarf, and this material carries with it the specific angular momentum of the donor star. For conservative mass transfer,

$$\dot{M} = (-\dot{P}/P)(M_{WD}M_{comp})/[3(M_{WD} - Mcomp)], \tag{10}$$

where P is the orbital period, $\dot{P}$ is the dimensionless time derivative of the period, M_{WD} is the mass of the white dwarf, and M_{comp} is the mass of the companion star. The period derivative equals twice the quadratic coefficient divided by the linear coefficient (of the cycle count N) in Equation 6, so $\dot{P} = 6.68 \times 10^{-10}$. With $M_{WD} = 1.3$ $M_{\odot}$ (Schaefer et al. 2010a) and $q = M_{comp}/M_{WD} = 0.20 \pm 0.03$ (Uthas et al. 2011), we have $\dot{M} = -3.5 \times 10^{-7}$ $M_{\odot}$ yr^{-1}. (The negative value for $\dot{M}$ implies that the companion star is losing mass, with the accretion rate often stated as the absolute value of this negative number.)

How does the accretion rate change when the conservative mass transfer parameters are changed? For ordinary accretion disks, some amount of angular momentum must be lost so that material can move from the outer to inner parts of the disk, with this likely being carried by a few per cent of the material being lost through the L2 point. Warner (1978) derives the period change as a result of this 'liberal mass transfer' case, which when applied to the T Pyx case predicts $\dot{M} = -9.9 \times 10^{-7}$ $M_{\odot}$ yr^{-1}. Warner (1978) also points to another case of liberal mass transfer plus mass loss, where mass falling onto the white dwarf is then ejected from the system, a situation that would arise from nova ejecta or jets. For T Pyx in this case, $\dot{M} = -7.1 \times 10^{-7}$ $M_{\odot}$ yr^{-1}. Patterson et al. (1998) point to another case for T Pyx, involving 'pure mass loss' where material is lost to the binary while carrying zero angular momentum. For T Pyx in this case, $\dot{M} = -2.5 \times 10^{-6}$ $M_{\odot}$ yr^{-1}. We now have four cases with varying conditions, and the real situation is likely to be sufficiently complex (see the next Section) that none of these four cases is exactly correct. Nevertheless, these four cases demonstrate the range of possibilities and the range of required $\dot{M}$ values. From this, we see that the conservative mass transfer case yields the lowest accretion rate, with alternative possibilities perhaps raising the accretion rate by up to one order of magnitude. (The presence of any angular momentum loss and consequent period decrease would only force the accretion rate to larger values.) From the physics of the T Pyx situation, the best estimate is likely the 'liberal mass transfer' case with $\dot{M} = -9.9 \times 10^{-7}$ $M_{\odot}$ yr^{-1}, and we can say with some confidence that the conservative mass transfer case is the lower limit so the accretion rate is $\geq 3.5 \times 10^{-7}$ $M_{\odot}$ yr^{-1}. This result can be represented by an accretion rate of $10^{-6.0 \pm 0.5}$ $M_{\odot}$ yr^{-1}.

Such an accretion rate appears to be very large, as it is near the limit for steady hydrogen burning (3×10^{-7} $M_{\odot}$ yr^{-1} for a near Chandrasekhar mass white dwarf; Nomoto et al. 2007;

Shen & Bildsten 2007). This limit is for accretion uniformly over the entire white dwarf surface, so any channelling of the material onto a small area near the polar cap (as in the case of an intermediate polar like T Pyx) will result in a *local* accretion rate that will have steady hydrogen burning. For any plausible accretion rate and any plausible polar cap area, the local accretion rate will be higher than the limit for steady hydrogen burning, and this provides the luminosity that makes T Pyx a V1500 Cyg type star (Schaefer & Collazzi 2010).

Method 2: The 2011 eruption ties the inter-eruption interval to 44 years. With this number, plus the approximate mass of the white dwarf, we can estimate the required trigger mass on the white dwarf and hence the accretion rate. A substantial problem is that the accumulated mass required for the trigger has a very strong dependence on the adopted conditions. It varies by over an order of magnitude over the acceptable range of white dwarf masses (Yaron et al. 2005), it varies by a factor of four over a plausible range of metallicities, and it varies by a factor of five over a plausible range of ^{3}He mass fraction (Shen & Bildsten (2007). In addition, the trigger mass varies by a factor of two with a change in $\dot{M}$ by a factor of ten over the plausible range. Nevertheless, for the estimated conditions, the T Pyx white dwarf must have accumulated $10^{-6.0\pm0.3}$ $M_\odot$ (Yaron et al. 2005), $10^{-6.3\pm0.2}$ $M_\odot$ (Nomoto et al. 2007) or $10^{-5.5\pm0.3}$ $M_\odot$ (Shen & Bildsten (2007) to be able to erupt. This range of theoretical models can be represented as $10^{-5.9\pm0.6}$ $M_\odot$. With the 44 year interval, we get the average rate of deposition of mass onto the white dwarf is in the range $10^{-7.5\pm0.6}$ $M_\odot$ yr^{-1}. This number represents a lower limit on the $\dot{M}$ value (which is the mass lost by the companion star) because perhaps substantial fractions of the material in the disk could be ejected rather then accumulating on the white dwarf surface. Also the fraction of hydrogen in the accumulated material might be low due to steady hydrogen burning. Importantly, this highly uncertain estimate is based on specific theoretical models, so we must be careful to not use this estimated $\dot{M}$ to evaluate future models.

Method 3: With our physical model for T Pyx (see Section 3), we can ask what accretion rate produces the observed brightness. That is, the system luminosity is tied to $\dot{M}$, so we can work from the observed B=15.5 mag (valid for most of the time during the last pre-eruption interval) and the distance (3.5±1.0 kpc) and change the $\dot{M}$ value until we get agreement. For this, our model includes a disk extending from 50% to 90% of the Roche lobe and reprocessing of the white dwarf light. We need accretion rates of $10^{-8.0\pm0.5}$ $M_\odot$ yr^{-1} for the plausible range of distances and radii for the inner edge of the disk. Selvelli et al. (2003) report a similar calculation based on the ultraviolet luminosity, deriving accretion rates from $2.2-4.6\times10^{-8}$ $M_\odot$ yr^{-1}. Selvelli et al. (2008) used a similar method to determine the accretion rates as $1.1\pm0.3\times10^{-8}$ $M_\odot$ yr^{-1}, while they also report on various relations between $\dot{M}$ and the V-band absolute magnitude to come up with similar accretion rates. These calculations all assumed that the system light is dominated by ordinary blackbody emission from the disk and companion star, whereas we have already seen that this cannot be. Therefore, these calculations are not relevant to T Pyx and the results can only be ignored.

Method 4: T Pyx is at best only a faint X-ray source, and this can be used to place limits on the accretion rate. Selvelli et al. (2008) report that their observations with *XMM-Newton* for 22.1 ksec in 2006 shows a faint source visible over the 0.2-8 keV energy range. The signal was too faint to allow for a reliable fit, but they demonstrate that a 200,000 K blackbody with 10^{37} erg s^{-1} source at 3.5 kpc is rejected because the spectrum below 0.5 keV would be roughly 300 times brighter than observed. For the soft X-ray component, this would imply an X-ray luminosity of roughly $10^{34.5}$ erg s^{-1}. Balman (2010) used the same *XMM-Newton* data set from 2006 (except she reports on effective exposure times of 30.6, 39.7, and 38.8 ksec for the three detectors). She found that an X-ray image shows an extended profile, with the unstated fraction of light above a single point source certainly coming from the shell around T Pyx. A spectral fit gives a luminosity of 6.0×10^{32} erg s^{-1} at a distance of 3.5 kpc over 0.3-10.0 keV. If this X-ray luminosity is taken to be the light from the accretion onto the white dwarf ($\frac{1}{2}GM_{WD}\dot{M}/R_{WD}$), then the accretion rate is 8×10^{-11} $M_{\odot}$ yr^{-1}. If the X-ray luminosity is taken to be from steady hydrogen burning of the freshly accreted material on the surface of the white dwarf ($0.007X\dot{M}c^2$ if all the hydrogen is burned, where X is the usual hydrogen fraction), then the accretion rate is around 2×10^{-12} $M_{\odot}$ yr^{-1}.

With these estimates from four different methods, the obvious problem is the contradiction between method 4 and all the other methods. The energetics of the 2011 eruption require a minimum mass to power the explosion and this was piled onto the white dwarf in 44 years, and this places a firm lower limit on the average rate of accumulation onto the white dwarf (from method 2). The accretion rate in 2006 was not far from the average from 1967 to 2011 (as measured by the B-band flux), so $\dot{M}$ must be greater than 2×10^{-9} $M_{\odot}$ yr^{-1}, and likely is much greater than this. With this, the accretion energy onto the white dwarf must be $> 2 \times 10^{34}$ erg s^{-1}, which is 20 times larger than the value from Balman (2010). (Balman evaluated this discrepancy to be a factor of 10-100.) So in all cases, the X-ray luminosity is greatly lower than the minimum required by the accretion energy simply coming from the X-rays. With steady hydrogen burning on the white dwarf, this discrepancy becomes even larger. Therefore, we know that most of the accretion luminosity is not coming out above 0.2 keV and therefore method 4 cannot be used to tell us the $\dot{M}$.

The question is now how to get the accretion (plus steady burning) luminosity to emit primarily below 0.2 keV. This can be done if the emission is from a blackbody with temperature <50,000 K. This fits well with the long-term ultraviolet spectrum from the *IUE* spacecraft (but not the optical or infrared spectrum) being well represented as a 34,000 K blackbody. Hence, the easy solution to the X-ray paucity observation is simply that the accretion-plus-burning energy is coming out as a 34,000 K blackbody.

What is the accretion rate in T Pyx? The first method (based on the $\dot{P}$) is robust with $10^{-6.0\pm0.5}$ $M_\odot$ yr^{-1}. This purely dynamical method, derived only from Kepler's Law and the conservation of angular momentum, is based only on timings of high confidence and accuracy, while being independent of the usual problems (distance, extinction, and emission mechanism). The second method (based on the theoretical trigger mass) yields an accretion rate $\geq 10^{-7.5\pm0.6}$ $M_\odot$ yr^{-1} and is also robust because it is based on simple energetics of the eruption, even though the exact value depends on the details of the model. The third method (reproducing B=15.5 mag from the disk) is unreliable because it assumes the usual thermal emission from disks and this cannot dominate the optical light for T Pyx. The fourth method (based on the X-ray luminosity) is also not useful because it gives such low values for $\dot{M}$ that cannot allow T Pyx to be recurrent, so only some very small and unknown fraction of the accretion luminosity can be coming out above 0.2 keV. Only the first two methods are useful. We favor the first method because something close to the 'liberal mass transfer' case must be the situation for T Pyx, and we do not think that any other mechanism can produce such a good parabolic O-C curve over two decades of time such that the orbital period is increasing. As a lower limit, the second method is in agreement with the first, although the limit is sufficiently far below the first method value that we expect that there must be some substantial inefficiency such as mass lost to the system from the accretion process or the partial burning of hydrogen on the surface of the white dwarf. So in all, we conclude that in recent decades the mass loss rate from the companion star has been $10^{-6.0\pm0.5}$ $M_\odot$ yr^{-1}, while the white dwarf has accumulated material at the rate of $\geq 10^{-7.5\pm0.6}$ $M_\odot$ yr^{-1}.

With $E = 1$, we can use the historical light curve to estimate the accretion rate at times outside the 1988-2008 interval. Before the 1890 eruption we have $\langle F_B \rangle = 7.59$, while the 1988-2008 interval has $\langle F_B \rangle$ close to 1.47 mag (Table 3). This means that the early accretion rate was 7.59/1.47=5.2 times the value from the last paragraph. So around 1890, the companion star lost mass at the rate of $10^{-5.3\pm0.5}$ $M_\odot$ yr^{-1}. Another application is that the years 1978-2004 have an average B=15.5 mag, while from 2005-2011, T Pyx had an average B=15.7 mag. This corresponds to a difference of a factor of 16% in blue flux, and hence a difference in $\dot{M}$ by 16%. This provides an explanation why the $\dot{P}$ changes around 2008 to a slightly smaller value. That is, as the white dwarf luminosity secularly fades, the irradiation-driven mass loss from the companion decreases, and the orbital period change decreases. So we can work backwards from the historical light curve through the accretion rate to the orbital period as a function of time. With this, the fairly constant brightness of T Pyx from 2005-2011 makes for a fairly constant $\dot{P}$ over this interval. For a short time interval, like from 2008-2011, the curvature in the O-C curve is negligible when simply extrapolating the orbital period from February 2011 to April 2011, therefore the pre-eruption orbital period from Section 4 (0.07622916±0.00000008 days) is still good.

7. The Nature of the Emission From Near the White Dwarf

T Pyx is a unique system, with its 1866 classical nova event that triggered the recurrent nova episodes, its very high accretion rate in a system with an orbital period of 1.83 hours, and its secular decline in brightness. There can be few stars in our Milky Way in this same state as T Pyx, but such rare systems have frequent eruptions to call attention to themselves from afar. T Pyx is also unique in the properties of the emission region near the white dwarf. The nature of this emission region has many possibilities and little theoretical understanding.

We have put a variety of constraints on the central emission region. First, we know that the optical light is optically thin, because the observed inter-eruption intervals require $F_B \propto \dot{M}$ which is impossible from a hot, optically thick source, and because the power law spectral energy distribution out to the infrared cannot come from any superposition of blackbodies within the Roche lobe. Second, we know that the accretion rate, i.e., the mass leaving the donor star, is roughly $10^{-6.0\pm0.5}$ $M_{\odot}$ yr^{-1} because the systematic and well-measured period *increase* from 1988-2008 cannot come from any cause other than the mass transfer, while the *dynamical* physics puts robust constraints on the accretion rate. Third, we know that the accumulation rate of material onto the white dwarf must be $\geq 10^{-7.5\pm0.6}$ $M_{\odot}$ yr^{-1}, because this is required to provide the trigger mass and the energy for the 2011 eruption. Fourth, we know that the region has a temperature that must be $\lesssim$50,000 K for an equivalent blackbody, because Balman (2010) used *XMM-Newton* to measure a limit on the X-ray luminosity of the central point source of 6.0×10^{32} erg s^{-1} for photon energies >0.2 keV. Fifth, the ultraviolet light is rising sharply towards the far ultraviolet as consistent with a 34,000 K blackbody and a luminosity of 2.9×10^{35} erg s^{-1} (corrected to 3.5 kpc), as based on the *IUE* spectral energy distribution (Selvelli et al. 2003). Sixth, the white dwarf has a magnetic field strong enough to disrupt at least the inner part of any disk and to channel the accretion onto a polar cap region, as shown by the unstable photometric periodicities near the orbital period reported by Patterson et al. (1998).

Based on the strong precedent of other novae and cataclysmic variables, the default idea would be to have the flux coming from some sort of a boundary layer of an accretion disk or an accretion column plus additional light from an accretion disk with reprocessing. But given the uniqueness of T Pyx, there is little confidence in this stereotype. Indeed, we know that this conventional picture must be far from correct. The $\dot{M}$ value is around $10^{-6.0}$ $M_{\odot}$ yr^{-1} being channeled onto a polar cap, so the default picture cannot explain the accretion region (Nomoto 1982). Also the power law spectral energy distribution in the optical and infrared cannot be produced by any disk and the absence of a Rayleigh-Jeans tail requires non-thermal emission processes in the optical region. With the failure of the conventional picture, we must look to alternative possibilities.

The mass falling off the donor star has a lot of energy that will be radiated at some wavelength. The total luminosity from $10^{-6.0}$ $M_{\odot}$ yr^{-1} falling onto the white dwarf ($GM_{WD}\dot{M}/R_{WD}$) is $10^{37.2}$ erg s^{-1}. Not all of this energy needs to leave the system as radiation if a substantial fraction of the material falling towards the white dwarf is ultimately ejected. If only $10^{-7.5}$ $M_{\odot}$ yr^{-1} makes it to the white dwarf, then the luminosity would be $10^{35.7}$ erg s^{-1}. The luminosity from complete hydrogen burning on the polar cap ($0.007X\dot{M}c^2$) is $10^{38.4}$ erg s^{-1} for the full accretion rate. The steady hydrogen burning cannot be complete because enough hydrogen must survive to make the nova eruption. In all, the accretion must provide a luminosity somewhere between $10^{35.7}$ and $10^{38.5}$ erg s^{-1}.

This accretion luminosity is easily identified with the flux seen by *IUE* from 120- 320 nm with an apparent blackbody temperature of 34,000 K. This temperature explains why essentially no X-ray flux is visible with *XMM*. If this emission is blackbody at a temperature of 34,000 K, then the wavelength of peak intensity would be 85 nm, so only a fraction of the light will appear in the *IUE* band. For a 34,000 K blackbody observed from 120-320 nm, the bolometric correction will be close to a factor of two. Applying this bolometric correction to the observed *IUE* luminosity gives $10^{35.9}$ erg s^{-1} as the luminosity of the central ultraviolet source. Thus, the observed *IUE* source can account for all of the accretion luminosity, if we keep to the lower end of the range. Thus, there is little steady hydrogen burning and a substantial fraction of the material fails to reach the white dwarf.

The luminosity and temperature points to the size of this ultraviolet-emitting region. For a 34,000 K blackbody equivalent with luminosity of $10^{35.9}$ erg s^{-1}, the surface area is that of a sphere with radius equal to 300,000 km. Such a volume is just smaller than the Roche lobe of the white dwarf. The coincidence of the volume required to produce the *IUE* source with the volume of the Roche lobe suggests that the binary orbit is somehow regulating the size of the emitting region.

If the emission region nearly fills the Roche lobe, then the orbital motion of the companion star will stir the outer material causing substantial amounts to be ejected from the system. This could account for the difference between the mass lost by the donor star and that accumulating on the white dwarf. Such tidal effects will also provide a steady change to the orbital period, even though we have no clear idea as to the magnitude or direction of such period changes.

It is unclear what fraction of this volume is optically thick. The inter-eruption intervals give something close to $F_B \propto \dot{M}$, so that the region must be optically thin. But an optically thin region might not produce enough luminosity. The *IUE* spectrum only shows a continuum that follows $F_\nu \propto \nu^{0.23}$ (Selvelli et al. 2003), so this could either be a portion of an optically thick blackbody or an optically thin power law. Presumably, this volume will be denser towards the white dwarf, so there will be some radius outside of which it is optically thin, while inside some photosphere it will be optically thick. Further, the very hot accretion column near the white dwarf surface would likely be smothered by surrounding material that is optically thick in the inner regions, with this material suppressing the X-ray emission (Selvelli et al. 2008; Balman 2010) and also causing for the observed ionization state of the lines during quiescence (Gilmozzi & Selvelli 2007).

The spectral energy distribution can be broken up into two components, the 34,000 K blackbody that dominates in the ultraviolet plus the $\nu^{0.9}$ power law that dominates in the optical and infrared. The power law component is from optically thin emission, with a possible contribution from a circumbinary disk in the infrared. This suggests that T Pyx will be ejecting substantial amounts of material, perhaps into a circumbinary disk, which should be relatively cool and optically thin. All of the physical details (e.g., temperatures, densities, ionization states, and distribution in space) will depend critically on the nature of the hot inner region. Therefore, we can only assert that it is reasonable for the thin outer regions are optically thin and produce the power law spectrum throughout the optical and infrared bands.

Our picture of the emission region (34,000 K, $10^{35.9}$ erg s^{-1}, the size of the Roche lobe) is without observational precedent among novae. Nevertheless, there is some theoretical anticipation that such an emission region could occur. In particular, when the accretion rate onto a white dwarf is between something like $10^{-6.3}$ to $10^{-5.3}$ M$_\odot$ yr^{-1} (for a 1.3 M$_\odot$ white dwarf with the accretion spread over the entire surface), a giant extended envelope will be formed around the white dwarf (Nomoto 1982). The T Pyx accretion rate ($10^{-6.0\pm0.5}$ M$_\odot$ yr^{-1}) is easily within this range. Not all of the material necessarily makes it to the surface of the white dwarf (perhaps $10^{-7.5\pm0.6}$ M$_\odot$ yr^{-1}), but all this material will be concentrated by the magnetic field onto a small pole cap, so that the *local* accretion rate will exceed the rate to start making a large envelope. The physics of this situation will be very complex, and no theoretical study has yet been made of rapid accretion forming an envelope over only a fraction of the surface of a white dwarf. On top of this, there is also the complex effects of the nearby companion star stirring this whole envelope not far above the white dwarf surface. Any detailed theoretical understanding must have a full study involving magnetohydrodynamics with a complex three-dimensional geometry involving nuclear burning on the surface, complex radiative transfer, and fast flows in many directions in a case where the key parameters (the accretion rate onto the white dwarf and the surface magnetic field strength) have large uncertainties. We think that the situation is sufficiently complicated and uncertain so as to defy even simple theoretical expectations from having any useful confidence. So we are largely left with the observational picture for providing any useful idea of the actual physical state of the emission region.

The observational picture of T Pyx shares some critical properties with one other cataclysmic variable, V Sge (Patterson et al. 1998). The effective temperature is 27,000-40,000 K and the optical-ultraviolet luminosity is $10^{37.0\pm0.5}$ erg s^{-1}. The X-ray luminosity of V Sge is 3×10^{32} erg s^{-1} from 0.1-3.5 keV with the preferred $kT < 0.3$ keV (Eracleous et al. 1991). V Sge has very strong blue colors and an ultraviolet excess, with B-V=-0.31 and U-B=-1.18 after reddening corrections. V Sge has eclipses in its light curve whose breadth is nearly half the orbital period, hence indicating that the hot region is comparable in size to the Roche lobe of the white dwarf. These observed properties all require an emission region similar to that sen in T Pyx. Eclipse timings over a many year interval yield a parabolic O-C curve with $P/\dot{P} = -5\times10^6$ years (Patterson et al. 1998). V Sge has its period *decreasing* (whereas T Pyx has its period *increasing*), but this is easily explained by the high mass ratio $q \sim 4$ (Herbig et al. 1965 give $M_{WD} = 0.7$ M$_\odot$ and $M_{comp} = 2.8$ M$_\odot$) so that the conservative mass transfer case implies an accretion rate of $10^{-7.2}$ M$_\odot$ yr^{-1}. This very high q (compared to all cataclysmic variables) readily explains why the accretion rate is so high, because any mass transfer only shrinks the Roche lobe of the donor star making for runaway accretion. With this, the cause for the high $\dot{M}$ in V Sge is completely different than in T Pyx. Another substantial difference between V Sge and T Pyx is that the V Sge white dwarf is far below the Chandrasekhar mass, and this explains why T Pyx shows frequent recurrent nova eruptions while V Sge has had no observed nova events. Nevertheless, despite greatly different evolutionary paths, both T Pyx and V Sge apparently have hot sources with high luminosity that fill up the Roche lobe around a white dwarf caused by an accretion rate close to that required to initiate steady hydrogen burning.

8. A Consistent Picture

T Pyx has a fairly complicated history that has been pieced together from a wide variety of data. It might be useful to have one consistent picture explicitly collected in one place. Here, we present a largely chronological summary based primarily on this paper, Schaefer (2010), Schaefer & Collazzi (2010), and Schaefer et al. (2010a).

The basic system parameters of T Pyx are a white dwarf mass of 1.30±0.05 M$_\odot$, a companion star mass of 0.26±0.04 M$_\odot$, an orbital period of 1.83 hr, and a nearly pole-on inclination. The white dwarf has a sufficiently strong magnetic field so that the accreting material will be channeled onto a polar cap, as with an intermediate polar. The distance is 3.5±1.0 kpc, and the extinction has $E_{B-V} = 0.25 \pm 0.02$ mag.

For ∼750,000 years before 1866, T Pyx was a nondescript short-period intermediate polar with an accretion rate of around 4×10^{-11} $M_{\odot}$ yr^{-1} and $B = 18.5$ mag. After this long and slow accumulation of mass on the white dwarf, a normal classical nova eruption occurred in the year 1866±5, reaching perhaps $B = 5$ mag. This eruption sent out a smooth shell with a mass of $\sim 10^{-4.5}$ $M_{\odot}$ (larger than the accumulated mass on the white dwarf) at a velocity of 500-715 km s^{-1}. This eruption irradiated the nearby companion star (which is very close due to the short orbital period) so as to drive a high rate of mass being pushed through the L1 point in the Roche lobe, with all this material being channeled by the white dwarf magnetic field into a small polar cap region. With some combination of the high accretion energy and steady hydrogen burning, the white dwarf remained as a hot high-luminosity source to continue the irradiation and keep the high $\dot{M}$ at a nearly self-sustaining rate. After the 1866 eruption was long over, T Pyx stayed as a bright high-accretion system, much in contrast to its state a few years previously. With its newfound high accretion rate, the white dwarf accumulated material quickly, and with it being near the Chandrasekhar mass, the system started producing recurrent novae events. Each successive recurrent nova eruption sent out a fast (2000 km/s) shell of relatively low mass ($\sim 2 \times 10^{-6}$ $M_{\odot}$), with these shells ramming into the slower 1866 shell causing thousands of knots to form by Rayleigh-Taylor instabilities. The feedback loop of irradiation and accretion is not stable, so the accretion rate must be declining, with the typical time scale for such cases being a century or so. With this, the accretion rate must decline, the brightness of the system must decline (as observed to fade from B=13.8 in 1890 to B=15.7 in 2011), and the overall recurrent nova phase (starting in 1866) must have a brief duration. Another consequence of the falling accretion rate is that the duration of the inter-eruption intervals must increase.

Three requirements are needed for this history to apply to T Pyx: a white dwarf near the Chandrasekhar mass, a short orbital period, and a significant magnetic field on the white dwarf. The combination of all three is rare, so there will be few such stars in our Milky Way and the duration of their recurrent nova phase will be short, perhaps one-to-a-few centuries out of millions of years. Nevertheless, their frequent and bright eruptions will call attention to these systems from far across the galaxy.

Although T Pyx is a system with material falling at a very high rate onto a white dwarf near the Chandrasekhar mass, it is not a progenitor of a Type Ia supernova. If the white dwarf is increasing in mass during the recurrent nova phase, stars like T Pyx cannot become the observed Type Ia supernovae because the former are by far too rare in our galaxy (and in the Andromeda Galaxy and the Large Magellanic Cloud) to account for the supernova rate. Also the duration of the recurrent nova phase is such a small fraction of the system's lifetime that this would be much too low to account for the supernovae. Whether the mass of the white dwarf is increasing or not over the recurrent nova cycle is inconsequential because the dynamics are greatly dominated by the classical nova eruption and these always eject more material than was accreted, so the white dwarf is actually *losing* mass. In general, all recurrent novae with short orbital periods (only T Pyx and IM Nor are known as such) are not the supernova progenitors because they have no mechanism to sustain the high accretion rate. The long orbital period recurrent novae (e.g., U Sco and RS Oph) can still be supernova progenitors because they have a mechanism (the evolution of the companion star off the main sequence) to sustain a steady high accretion rate onto the white dwarf.

The irradiation of the low mass companion star causes a high accretion rate, which is measured to be $10^{-6.0\pm0.5}$ $M_\odot$ yr^{-1} as based on the fast and steady increase in the orbital period since the middle 1980's. With all this material being channelled onto a small polar cap, the local accretion rate will be so large that an extended envelope will form around the accretion column. The physics of the situation is very complex and has not yet been explored, but the observed result is a hot envelope that fills up the entire Roche lobe of the white dwarf. This hot envelope is seen in the ultraviolet by *IUE* as having a spectrum like a 34,000 K blackbody and a luminosity of $10^{35.9}$ erg s^{-1}. The $\nu^{0.9}$ power law in the optical and infrared spectrum comes from the optically thin outer parts of the central region plus from the diffuse material outside the Roche lobe that has been ejected by the close-in companion star. With the optical light being from an optically thin region, the observed flux will be proportional to the mass accretion rate. As such, the 22 year inter-eruption interval before 1967 (with $\langle B \rangle = 14.70$ mag) has a flux roughly a factor of two brighter than the inter-eruption interval after 1967 (with $\langle B \rangle = 15.59$ mag), so its duration should be roughly 2×22 years and the next eruption around the year 2011.

The eruption after 1967 was widely expected starting in the mid-1980's. No eruption could have been missed (say, due to solar gaps) because the recurrent nova events have a long duration (roughly 230 days, with $t_3 = 62$ days) and a bright peak (B=6.7 mag) such that the nightly observations throughout the entire observing season would certainly have caught any eruption. Nevertheless, many observers in the professional and amateur communities persevered by taking many time series and nightly monitoring for decades on end. From 1986-2011, the orbital period had a steady increase at $P/\dot{P} = +313,000$ years, although a small deviation appears from 2008-2011 as expected for the small observed drop in accretion luminosity over this time. In the several years before 2011, T Pyx averaged V=15.5 mag, and was never seen brighter than V=15.0.

It came as a surprise to Stubbings when T Pyx appeared at V=14.5 on UT 2011 April

5.51, and he realized that this might presage an eruption. Instead, he saw a unique rise and fall in brightness with a peak at V=14.4 over several days. This pre-eruption rise started just 11 days before the eruption. Only four anticipatory rise/dips have ever been seen (T Pyx, , with all being greatly different from each other, and all with zero theoretical understanding.

As part of his long series of monitoring of recurrent novae, Linnolt saw T Pyx at V=14.5 on UT 2011 April 13.36 and realized that this was unusually bright. On the next night at UT 2011 April 14.29, Linnolt saw T Pyx at V=13.0 and immediately recognized the eruption. Within 15 minutes the world had been alerted, Plummer and Kerr soon confirmed the eruption, and Nelson, Carstens, and Streamer started time series in BVI. For the first two days, the magnitude during this initial rise is closely represented as that of a uniformly expanding shell. The steady and frequent monitoring, principally by amateur observers, fast recognition and notification, and speedy response around the world all make for T Pyx being the first and only nova eruption where the light curve was followed throughout the entire initial rise.

This work is supported under a grant from the National Science Foundation. AUL acknowledges support from NSF grants MPS 75-01890 and AST 0803158, and from AFOSR grants 77-3218 and 82-0192. AP is supported by the Edward Corbould Research Fund and the Astronomical Association of Queensland. MS wishes to thank the AAVSO for the loan of the SBIG 402 camera. WGD thanks Arne Rosner at Global Rent-A-Scope in Moorook, South Australia. Throughout this work, the AAVSO provided charts, comparison sequences, data archiving, and alert notices.

Table 1. Pre-eruption Rises and Dip

Nova	Nova Class[a b]	V_{peak}[a]	V_Q[a]	V_{rise}[c]	ΔT (days)[c d]	Rise Morphology[c]
T Pyx	P(62), RN, IP, short-P_{orb}, shell	6.4	15.5	14.4	11	'Bump'
V533 Her	S(43), CN, IP, shell	3.0	15.0	13.3	550	Exponential rise
V1500 Cyg	S(4), neon CN, Polar, shell	1.9	20.5[c]	13.5	>23	Fast and bright rise
T CrB	S(6), RN, Red Giant donor	2.5	9.8	10.8	380	*Dip*, variable depth and color

[a] Data from Strope, Schaefer, & Henden (2010).

[b] Class P has a plateau in the light curve. Light curve class S has a smooth monotonic decline. The parentheses contains the t_3 decline rate. CN indicates a classical nova with no known recurrences. IP indicates an intermediate polar system with a highly magnetized white dwarf star.

[c] Data from Collazzi et al. (2009) and this paper.

[d] ΔT is the time from the beginning of the pre-eruption rise (or dip) to the start of the eruption.

Table 2. T Pyx in quiescence (1890-2011) and the initial rise of the 2011 eruption

Julian Date	Band	Magnitude	Source
2411491	B	13.80 ± 0.15	HCO plates
2411493.6	B	13.80 ± 0.30	HCO plates

[c] AAVSO data base

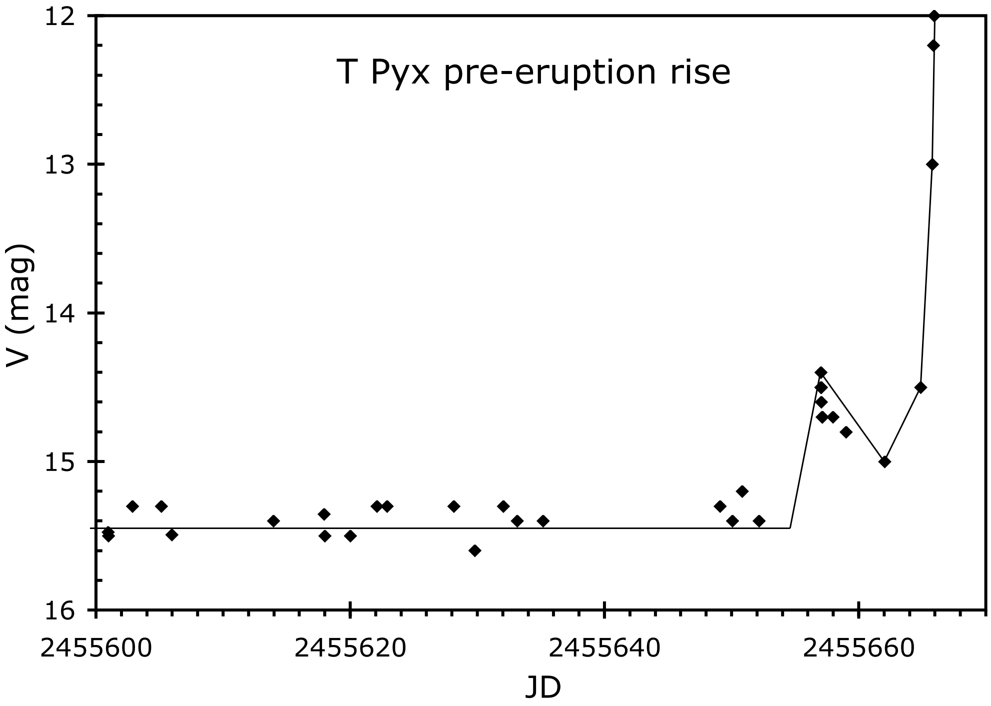

Fig. 1.— Pre-eruption rise. T Pyx never appeared brighter than V=15.0 for thousands of days before the eruption, and then it suddenly brightened to V=14.4 mag just 11 days before the eruption. (Further magnitudes from the *All Sky Automated Survey* are not shown here due to the apparent offset, yet they indicate that the duration is roughly 4 days for the pre-eruption rise.) The close time coincidence and the uniqueness of the bump demonstrate some causal connection between the bump and the eruption. The decline before the very fast rise demonstrates that this significant bump in the light curve is not some early part of the thermonuclear runaway. There is no understanding of the cause of the bump or why it anticipates the eruption. Explaining the pre-eruption phenomena is now a premier challenge for nova theory.

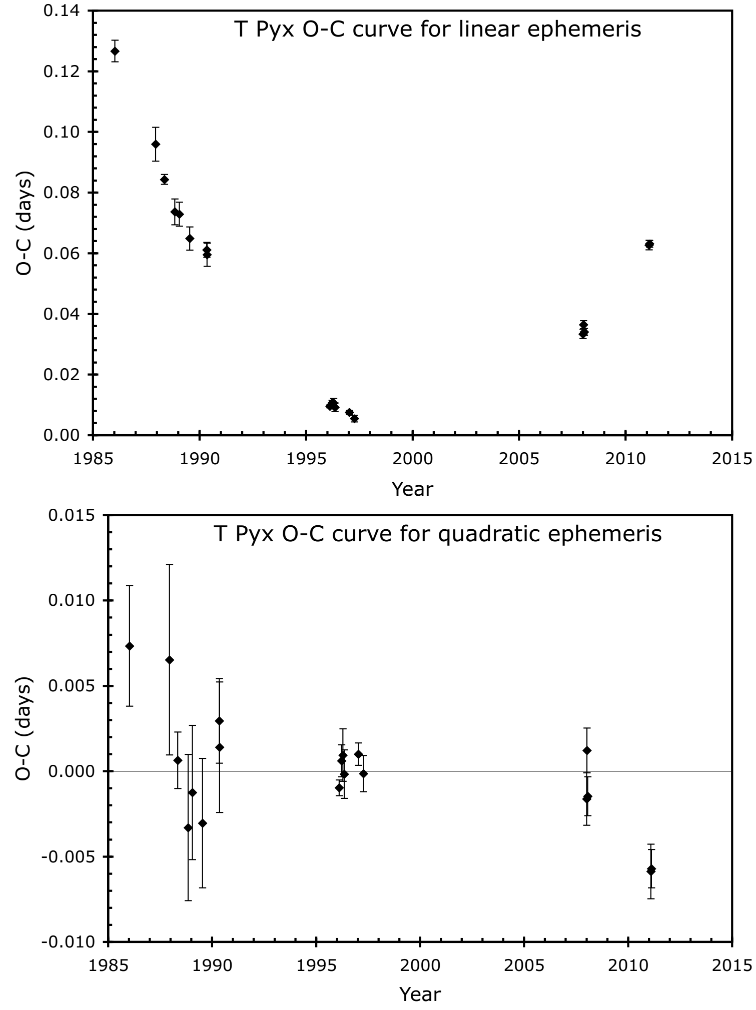

Fig. 2.— T Pyx O-C curve. T Pyx has a stable periodic modulation in its light curve, and we have minimum times from 1986 until February 2011 (just 48 days before the eruption). The upper panel shows the O-C curve for a linear ephemeris (Equation 6 with the quadratic term set to zero), in which we see a closely parabolic shape. This indicates that T Pyx has a steady change in orbital period, just as expected for steady conservative mass transfer at a rate of 3.5×10^{-7} $M_\odot$ yr^{-1}, although this can only be a lower limit. The lower panel shows the O-C curve for the predicted times coming from the quadratic ephemeris of Uthas et al. (2011). This steady period change well describes the minimum times from 1988 to 2008. But the two minimum times from February 2011 are consistent and highly significantly below the predictions of Equation 10, so apparently T Pyx underwent some sort of a small period change soon after 2008, such that its orbital period just before the 2011 eruption is slightly different (7.5 parts per million) from the period given by Equation 6. Such a change in $\dot{P}$ is expected due to the observed 16% decrease in system brightness (and hence a 16% decrease in accretion rate) from 2005-2011.

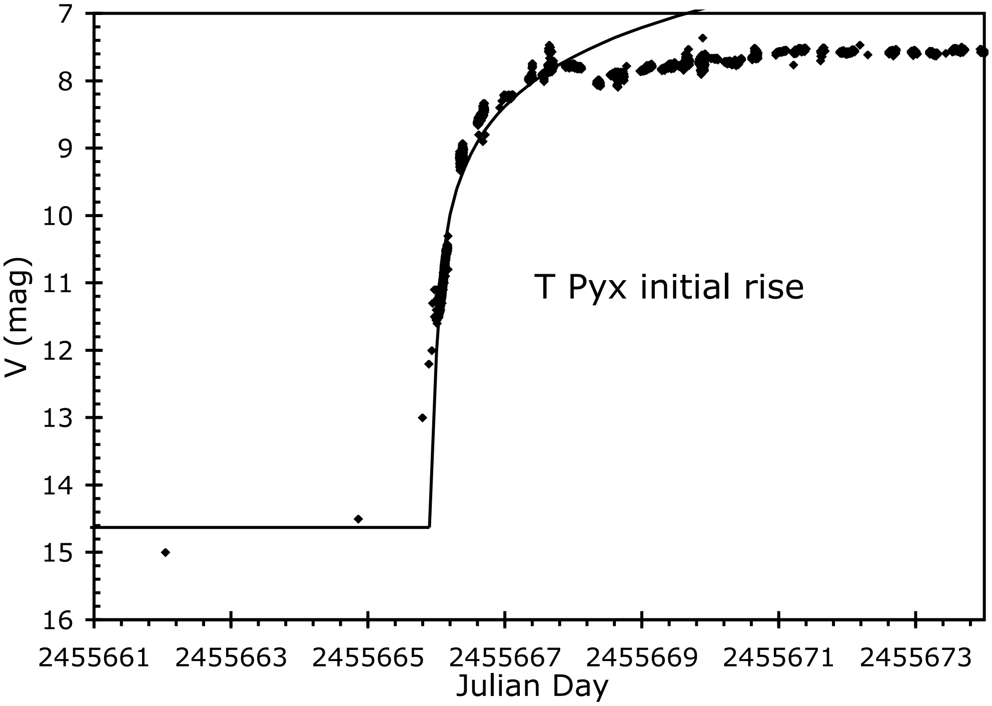

Fig. 3.— Initial rise. T Pyx now has the only nova light curve where the brightness was followed over the entire initial rise. For the first time, we see that the initial rise starts suddenly and is very fast. The rise is as fast as 9 magnitudes per day. A uniformly expanding shell is expected to rise fast in brightness followed by a substantial slowing (in magnitude units) after the first day, with the best fit model displayed by the curve in the figure. We see a sudden small fading and break from the model about two days after the start, with this perhaps indicating the recession of the photosphere.

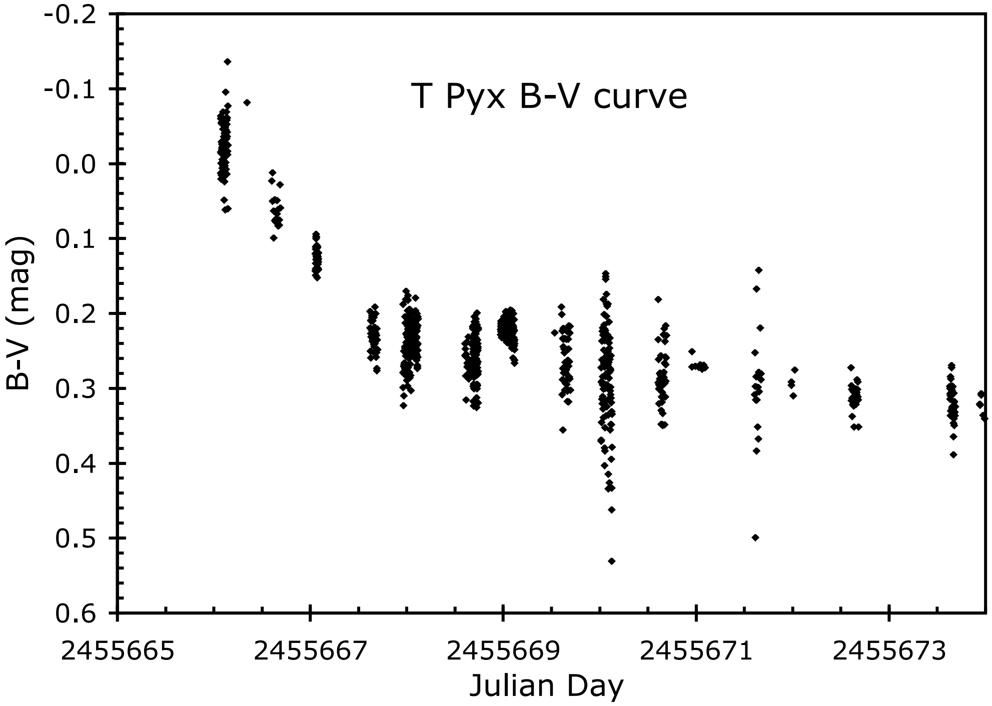

Fig. 4.— B-V color over initial rise. We also have the first and only measure of the colors of the initial rise of a nova. The color does change somewhat over the first two days of the eruption (covered by the model fit in Figure 3), suggesting that the photospheric temperature does change over this interval, with this being contrary to the simple model of a uniform expanding shell with a constant temperature. The initial colors ($B - V = -0.02$ and $V - I = +0.39$) are not those of a blackbody.
